

Canaries

- The compiler modifies every function's prologue and epilogue regions to place and check a value (a.k.a a canary) on the stack
- When a buffer overflows, the canary is overwritten. The programs detects it before the function returns and an exception is raised
- Different types:
 - random canaries
 - xor canaries
- Disabling Canary protection on Linux
`$ gcc ... -fno-stack-protector`
- Bypassing canary protection : *Structured Exception Handling (SEH)* exploit overwrite the existing exception handler structure in the stack to point to your own code

DEP/NX - Non Executable Stack

- The program marks important structures in memory as non-executable
- The program generates an hardware-level exception if you try to execute those memory regions
- This makes normal stack buffer overflows where you set `eip` to `esp+offset` and immediately run your shellcode impossible
- Disabling NX protection on Linux
`$ gcc ...-z execstack`
- Bypassing NX protection : *Return-to-lib-c* exploit
return to a subroutine of the lib C that is already present in the process' executable memory
